# Montreux 2007

# Overview

In this study, plasma and urine samples were taken from two Zucker rat strains and analyzed by using electrospray in positive and negative ion mode (electrospray ionization resulted in a far higher number of ion signals compared to APCI). Profiling software and Principal Component Analysis (PCA) was used not only to establish the differences between the two rat strains but also to highlight specific endogenous metabolites that could account for the PCA data.

A quadrupole ion trap mass spectrometer was applied to lipid profiling on biological samples derived from two Zucker rat strains (the Zucker (fa/fa) obese, which is a leptin deficient mutant, and the wild type, which is normal). To validate the assignments of lipid species based on both mass accuracy in MS and MSn data streams, a formula prediction software tool was used to determine the lipid profile distributions between the two rat strains.

### Introduction

Mass spectrometry (MS) has been shown to be a powerful tool in elucidating the diversity of lipid species and their participation in regulating cellular functions particularly in biomarker discovery research. In recent years, high mass accuracy mass spectrometry has been increasingly utilized, particularly in profiling global lipid distribution to help differentiate lipid species (to assign chemical compositions for lipid mass accuracy better than 21ppm is required, Jones et al, 2004). To help identify individual lipid molecular species public domain databases (DBs) play an important role in componen verification (for example http://lipidsearch.jp or http://metlin.scripps.edu/metabo\_list.php.

By bringing together high mass accuracy MSn analysis with formula prediction software, identifying endogenous metabolites in profiling studies can be assigned with greater certainty even in the presence of a complex biological matrix.

### Methods

Plasma and urine samples were taken from two Zucker rat strains (the Zucker (fa/fa) obese, which is a leptin deficient mutant, and the wild type, which is normal). Components were separated using a gradient elution into a LCMS-IT-TOF mass spectrometer (quadrupole ion trap-time of flight MS) (Shimadzu Corporation, Japan) using electrospray ionization (ESI), scanning 200-850 m/z in MS and between 50-850 in MS<sup>n</sup> mode. The chromatographic system used a binary solvent system used a binary solvent system used a binary solvent system. delivered as a gradient of Solvent A (formic acid solution 0.1%) and Solvent B (acetonitrile), and used a Shim-Pack XR ODS, 2 1v100 mm

Profiler software (Phenomenome Informatics) was used to create a data array for all sample data; this tool was used to highlight specific components that were statistically different between the two rat strains and to export data to SIMCA-P (Umetrics) for PCA analysis.

### Figure 1

Profiler software was used to transform LC/MS raw data into a data array of retention time and mass pairs. The data array was then normalized to highlight differences in component identities between the Zucker (fa/fa) obese, which is a leptin deficient mutant, and the wild type, which is normal.

# A 18 Zucker (fa/fa) obese Wild type Rat strain Rat strair 2 3 4 5 6 7 8 R2X[1] = 0.559543 R2X

Figure 2. PCA discriminates between the two rat strains (the Zucker (fa/fa) obese, which is a leptin deficient mutant, and the wild type, which is normal). The difference between the two clusters reflects a different distribution of plasma phospholipid concentrations.

0.0 1.0 2.0 3.0 4.0 5.0 6.0 7.0 8.0 9.0 10.0 11.0 12.0 13.0 14.0 15.0

Figure 3. Mass chromatogram range between m/z 450-550 for the Zucker (fafa) obese (upper chromatogram) and wild type (lower chromatogram) normalised to the same intensity. The distribution of phospholipids is the same between the two strains, the difference in PCA is with the ion signal intensity between the groups.

## Component identification

Predicting a candidate list based on MS and MSn data takes into account mass accuracy and mass resolution of the experimentally derived pseudomolecular peak and related fragment ion data generated using MSn spectra (or complement ion data) together with conventional chemical rules (such as nitrogen, electron configuration, DBE range, H/C ratio).

Figure 4. Formula prediction software used to help identify the component at 7.347 minutes. The most probable empirical formula for the component was  $C_{\rm 24}H_{\rm 50}NO_{\rm 7}P$ . Using public databases this formula corresponded to 1-Palmitoyllysophosphatidylcholine. The same approach was used to identify all other lipids components in the plasma samples in both populations

# Positive identification using high mass accuracy

Using the formula prediction software a number of phospholipid components were positively identified (the Components showed a strong agreement with published high mass accuracy data for MS and MS/MS and also showed the same fragment ions as the public databases)

Figure 5. A series of lipids were identified using the formula prediction software. In all instances the predicted formula was the first hit; in most instances only one candidate was reported illustrating the usefulness of the MSn as a candidate filter in plasma and urine samples.

# Conclusions

Although profiling studies are useful tools in biomarker research it is also important to provide positive identification for specific components. Using high mass accuracy MSn data with a software tool that calculates empirical formula assignments helps to increase the probability of positive identification using LC/MS.
